Morphological Characterisation of Basally located Uninucleate Trophoblast Cells as  
Precursors of Bovine Binucleate Trophoblast Giant Cells

Abstract

Binucleate trophoblast giant cells (TGCs) are one characteristic feature of the ruminant placenta. In cows, the frequency of TGCs remains constant over most time of pregnancy. As TGCs are depleted by their fusion with uterine epithelial cells, they need to be constantly formed while it is unclear whether they develop from stem cells (SCs) within the trophoblast or whether they can arise from any uninucleate trophoblast cell (UTC). Within the latter theory, basally located uninucleate cells (BUCs) without contact to the feto-maternal interface would represent a transient cell between UTCs and TGCs. So far, no evidence for the existence of such transient cells or of SCs has been shown. The aim of the present study is to morphologically characterize early stages of TGC development. Placentomal tissue of 6 pregnant cows from different gestational stages (gestational days 51 - 214) was examined for BUCs, UTCs and TGCs either in serial sections (light and transmission electron microscopy (LM, TEM), n = 3), in single sections (TEM, n = 2) or by serial block face-scanning electron microscopy (SBF-SEM, n = 1). These investigations revealed the occurrence of BUCs as well as young basally located TGCs showing contact to the basement membrane (BM), but without apical contact to the feto-maternal interface. The study morphologically defines these two cell types as early stages of TGC development and shows that binucleation of TGCs can precede detachment from the BM.

Morphologische Charakterisierung von Basal gelegenen Uninukleären Trophoblastzellen als Vorläufer von bovinen binukleären Trophoblastriesenzellen

Zusammenfassung

Binukleäre Trophoblastriesenzellen (BTZs) sind ein Charakteristikum der Wiederkäuerplazenta. Der BTZ-Anteil im Trophektoderm bleibt während langer Trächtigkeitsphasen konstant, wobei die BTZs durch Fusion mit uterinen Epithelzellen kontinuierlich zugrunde gehen. Dies setzt eine andauernde BTZ-Produktion voraus. Es wird diskutiert, ob die BTZs aus Stammzellen (SZs) im Trophektoderm oder aus normalen uninukleären Trophoblastzellen (NUZs) entstehen, wobei eine basal gelegene, uninukleäre Zelle (BUZ) ohne Kontakt zum maternalen Epithel eine Übergangszelle zwischen einer NUZ und einer BTZ darstellt. Beweise für die Existenz einer BUZ oder einer SZ wurden jedoch bisher nicht gezeigt. Das Ziel dieser Studie ist es, frühe Stadien der BTZ-Entwicklung morphologisch zu charakterisieren. Plazentomgewebe von 6 tragenden Kühen (Trächtigkeitstag 51 – 214) wurde licht- und transmissionselektronenmikroskopisch in Serienschnitten (n = 3), in Einzelschnitten (n = 2) oder im „serial block face-scanning electron microscope“ (n = 1) auf BUZs, NUZs und BTZs untersucht. Diese Untersuchungen bestätigten die Existenz von BUZs sowie von jungen, basal gelegenen BTZs mit Kontakt zur Basalmembran (BM) aber ohne Kontakt zum maternalen Epithel. Diese zwei Zelltypen werden anhand von morphologischen Kriterien als frühe Stadien der BTZ-Entwicklung interpretiert. Zudem wurde gezeigt, dass die Ablösung von der BM während der BTZ-Entwicklung nicht vor Erlangen eines binukleären Stadiums abgeschlossen sein muss.

### 35 **Abstract**

36 Binucleate trophoblast giant cells (TGCs) are one characteristic feature of the ruminant  
37 placenta. In cows, the frequency of TGCs remains constant over most time of pregnancy. As  
38 TGCs are depleted by their fusion with uterine epithelial cells, they need to be constantly  
39 formed while it is still unclear whether they develop from stem cells (SCs) within the  
40 trophectoderm or whether they can arise from any uninucleate trophoblast cell (UTC). Within  
41 the latter, generally accepted theory, a basally located uninucleate cell (BUC) without contact  
42 to the fetomaternal interface would represent a transient cell between a UTC and a TGC. So  
43 far, no evidence for the existence of such transient cells or for the presence of SCs has been  
44 shown. The aim of the present study is to morphologically characterize early stages of TGC  
45 development. Placental tissue of 6 pregnant cows from different gestational stages  
46 (gestational days (gd) 51 - 214) was examined for BUCs, UTCs and TGCs either in serial  
47 sections (light and transmission electron microscopy (LM, TEM), n = 3), in single sections  
48 (TEM, n = 2) or by serial block face-scanning electron microscopy (SBF-SEM, n = 1). These  
49 investigations revealed the occurrence of BUCs, as well as young TGCs showing contact to  
50 the basement membrane (BM), but without apical contact to the fetomaternal interface. The  
51 study morphologically defines these two cell types as early stages of TGC development and  
52 shows that binucleation of TGCs can precede detachment from the BM.

61 **Introduction**

62 The trophoblast epithelium of the bovine placenta consists of uninucleate trophoblast cells  
63 (UTCs) and trophoblast giant cells (TGCs), also called binucleate trophoblast cells (BNCs)  
64 [Björkmann, 1969; Klisch et al., 1999a; Klisch et al., 1999b]. These two cell types are  
65 characteristic elements of the ruminant fetal placenta [Hoffman and Wooding, 1993; Wooding  
66 and Burton, 2008] with a morphology that is largely uniform within the different ruminant  
67 species [Wooding, 1992].

68 UTCs show a cuboidal to columnar shape [Wathes and Wooding, 1980], have contact to the  
69 trophectodermal basement membrane (BM) [Wimsatt, 1951] and their microvilli interdigitate  
70 with those of the uterine epithelial cells [Björkmann, 1969; Wathes and Wooding, 1980]. The  
71 cytoplasm shows polysomes, rough endoplasmic reticulum (rER) and a small Golgi  
72 apparatus. Their numerous mitochondria are located in the apical part of the cell while lipid  
73 droplets and vesicles of different size are situated near the BM [Björkmann, 1969; King et al.,  
74 1980].

75 TGCs are migrating cells, which develop in the basal part of the trophoblast epithelium  
76 [Wimsatt, 1951; Morgan and Wooding, 1983] and move apically to the feto-maternal contact  
77 zone to fuse with the uterine epithelium [Wathes and Wooding, 1980; Wooding and Wathes,  
78 1980; Wooding, 1983]. Young, basally located TGCs [Wimsatt, 1951; Morgan and Wooding,

1983] do not have contact to the BM nor to the feto-maternal border [Hoffman and Wooding, 1993]. They possess a rounded shape and show a great amount of cytoplasmic ribosomes [Björkmann, 1968; Wooding, 1992]. Mature, apically migrating TGCs have an increased cell as well as nuclear volume [Morgan and Wooding, 1983; Wooding, 1992; Klisch et al., 1999b] and show numerous small mitochondria, plenty of rER and a large Golgi apparatus [Björkmann, 1968; Morgan and Wooding, 1983; Wooding, 1992]. They contain a remarkable amount of membrane-bound granules, which incorporate a variety of secretory proteins [Wooding and Beckers, 1987; Zoli et al., 1992; Klisch and Leiser, 2003]. Additionally, they possess a special organelle called double lamellar body (DLB), which has been claimed to be characteristic for TGCs while its function has not been described yet [Wooding and Burton, 2008].

The production of the cytoplasmic membrane-bound granules, which contain placental lactogen (PL) [Wooding and Beckers, 1987], prolactin-related protein-I (PRP-I) [Klisch and Leiser, 2003] and pregnancy-associated glycoprotein (PAG) [Zoli et al., 1992; Klisch and Leiser, 2003], displays an important function of TGCs. In cattle, the fusion of a TGC with a uterine epithelial cell forms a feto-maternal hybrid cell, which delivers the content of the cytoplasmic granules to the maternal tissue and circulation by basal exocytosis [Wathes and Wooding, 1980; Wooding, 1983; Wango et al., 1990]. As the feto-maternal hybrid cell degenerates after having transferred the content of the granules into the maternal tissue [Wooding and Wathes, 1980; Hoffman and Wooding, 1993], this protein delivery process implies a reduction of TGC number in the fetal tissue. However, their fraction within the trophoctoderm is relatively consistent at about 20 % until the end of gestation [Wooding and Wathes, 1980]. Thus, a constant production of TGCs during pregnancy is required.

The origin of TGCs has been discussed by different authors, but is still not fully clarified. Wimsatt [1951] identified mature TGCs as “post-mitotic” cells due to the absence of cleavage-furrows in any TGC. He described the development of these cells by transforming

UTCs, which acquire a round shape, lose contact to the BM and become binucleate by acytokinetic mitosis [Wimsatt, 1951].

Greenstein et al. [1958] described an undifferentiated, polygonal to cuboidal cell type in the peri-implantational trophoctoderm, which he construed to be a stem cell for both UTCs and TGCs [Greensteine et al., 1958].

The most recent and widely accepted theory about the origin of TGCs has been established by Wooding and his co-authors [Wooding, 1992; Wooding and Burton, 2008]. They suggest that any typical UTC can perform an asymmetric mitosis. One daughter cell of this mitosis is a basally located uninucleate cell (BUC), which subsequently develops into a TGC by losing contact to the BM and getting binuclear by an acytokinetic mitosis.

Despite these concepts have frequently been referred [Klisch et al., 1999a; Klisch et al., 1999b; Klisch and Leiser, 2003; Igwebuike, 2006; Haeger et al., 2016], to our knowledge, no evidentiary images for the existence of such a basally located uninucleate transient or stem cell in the mature bovine placenta have been published.

Thus, the aim of this study is to verify the existence of BUCs and to characterize the early stages of TGC development in cows morphologically. To settle these questions, amongst others, an automated serial sectioning technique (serial block face-scanning electron microscopy [SBF-SEM]), will be used.

## **Materials and Methods**

### **TISSUE PREPARATION**

Placental tissue was collected from 6 pregnant cows (gestational day (gd) 51, 109, 120, 140, 158 and 214) at a local slaughterhouse. Uteri were obtained approximately 30 min after death of the cow by bolt shoot and exsanguination. The gestational stage was estimated based on the measured fetal crown-rump length [Schnorr and Kressin, 2011].

130 Tissue from 5 of these cows (gd 51, 109, 120, 140, 214) was prepared for light microscopy  
131 (LM) and conventional transmission electron microscopy (TEM). One randomly chosen  
132 placentome was perfused with 20 ml 2.5 % glutaraldehyde in 0.1 M sodium/potassium (Na/K)  
133 phosphate buffer. For this perfusion, a fetal placental blood vessel close to the chosen  
134 placentome of the opened uterus was clipped with the tip of small scissors, a blunt 21G  
135 butterfly winged cannula (B. Braun Venofix 21G Butterfly Winged Cannula Needles, B.  
136 Braun Melsungen AG, Melsungen (Hessen), D) was introduced into the vessel and fixed with  
137 haemostats to the surrounding tissue to hold it in position. Then, perfusion was performed  
138 manually with soft pressure by a 20 ml syringe during 1-2 min without any pre-washes. A  
139 slice of 1 – 2 mm thickness and ranging from the top to the bottom of the placentome was cut  
140 out centrally of the placentome with a sharp razorblade and was trimmed to cubes of 1 - 2 mm  
141 side lengths with the same razorblade. These cubes were immersed in the same fixative as  
142 used for perfusion during 1h at 0 - 4°C. After fixation, the tissue was stored in cold 0.1 M  
143 Na/K phosphate buffer until it was postfixed with 1 % osmium tetroxide in 0.1 M Na/K  
144 phosphate buffer, dehydrated in a graded series of ethanol and embedded in epon. If  
145 necessary, the tissue cubes were trimmed to a size of 1 mm side lengths before postfixation.  
146 For serial block face-scanning electron microscopy (SBF-SEM) one placentome of a pregnant  
147 cow (gd 158) was perfused with 20 ml 2.5 % glutaraldehyde and 2 % formaldehyde in 0.15 M  
148 cacodylate buffer (pH 7.4) containing 2 mM calcium chloride (CaCl<sub>2</sub>). Perfusion was  
149 performed in the same way as perfusion of the tissue for LM and TEM. A slice of 1 – 2 mm  
150 thickness and ranging from the top to the bottom of the placentome was cut out centrally of  
151 the placentome with a sharp razorblade and was trimmed to cubes of 1 - 2 mm side lengths  
152 with the same razorblade. These cubes were immersed in the same fixative as used for  
153 perfusion during 3h at 0 - 4°C. Following fixation, the tissue was washed (4 x 3 min) in cold  
154 0.15 M cacodylate buffer containing 2 mM CaCl<sub>2</sub> on a shaker and then stored in fresh buffer  
155 at 4°C until further processing. If necessary, the tissue cubes were trimmed to a size of 1 mm

side lengths before they were further treated following a protocol optimised for SBF-SEM [Deerinck et al., 2010]. Tissue embedding was mainly performed as described in this protocol except of two modifications: using an epon mixture with a harder consistence (3.63 g epoxy embedding medium (Fluka, Sigma-Aldrich Chemistry GmbH, Buchs, CH) + 2.63 g NMA (Nadic methyl anhydride, Fluka, Sigma-Aldrich Chemistry GmbH, Buchs, CH) + 1.25 g DDSA (Dodecenyl succinic anhydride, Fluka, Sigma-Aldrich Chemistry GmbH, Buchs, CH) + 0.14 g DMP-30 (2,4,6-Tris(dimethylaminomethyl)phenol, Fluka, Sigma-Aldrich Chemistry GmbH, Buchs, CH) for approximately 6 ml epon), which has been polymerized at 60°C during 2.5 days, and using Easy-Molds (EMS, Pennsylvania, USA).

## SERIAL SECTION EXAMINATION

### Light microscopy (LM)

Serial semithin sections (1  $\mu$ m) were cut from tissue blocks of 3 animals (gd 51, 140 and 214) with an ultramicrotome (Ultracut E, Reichert, Vienna, AT), mounted on glass slides (Menzel-Gläser, Braunschweig, D) and stained with toluidine blue. Alternating, sections were either coverslipped in Pertex (Medite, Burgdorf, D) or left without a coverslip. Within the series of covered sections, several cells were followed and photographed with a light microscope. On the basis of the photographs, the cells were categorized in three groups: UTCs, which light microscopically were located on the BM and showed contact to the fetomaternal interface, TGCs, which exhibited two nuclei, or BUCs, which light microscopically did not show contact to the fetomaternal interface.

The nuclear volume of all examined cells was estimated according to the principle of Cavalieri [Mayhew, 1991] with the Stereoinvestigator software (MBF Bioscience, Williston, VT). In TGCs, the nuclear volumes of all nuclei in 1 cell were summed up as a total nuclear volume (TNV).

## Transmission electron microscopy (TEM)

From each series of semithin sections, five non-coverslipped sections, with a distance of 6  $\mu\text{m}$  (5 sections) between each other, were re-embedded in epon. Re-embedding was performed according to the protocol described by Suzuki et al. [2003], while instead of BEEM capsules [Suzuki et al., 2003] Easy-Molds (EMS, Pennsylvania, USA) were used. The re-embedded sections covered segments of the series where most of the light microscopically examined cells were located. After re-embedding, ultrathin sections (70 nm) were cut with an ultramicrotome (Ultracut E, Reichert, Vienna, AT), mounted on slot grids with formvar (EMS, Pennsylvania, USA) or polystyrene 2'000'000 g/mol membrane (0.5 g of polystyrene solved in 100 ml chloroform) and stained with uranyl acetate and lead citrate. The in LM examined cells were followed within the ultrathin sections with a transmission electron microscope (CM12, Philips, Eindhoven, NL) and photographs were taken with a CCD camera (Ultrascan 1000 or Orius 832, Gatan, Pleasanton CA, USA). By means of the photographs the cells were assessed regarding following criteria:

- contact to the BM
- contact to the feto-maternal interface
- presence of membrane-bound granules
- occurrence of particular organelles (DLB, mitochondria and free cytoplasmic ribosomes in all three cell types and Golgi apparatus and rER only in UTCs and BUCs)

In cases where none of the ultrathin sections of one semithin section were investigable due to rupture of the membrane or insufficient contrasting, an adjacent semithin section without coverslip was re-embedded, sectioned and examined.

## Statistical Methods

Statistical analysis of the estimated nuclear volumes was done with SPSS 23 (IBM® SPSS® statistics, version 23.0, IBM Corp., USA).

## SINGLE SECTION EXAMINATION

### Transmission electron microscopy (TEM)

Ultrathin sections (70 nm) were cut from tissues of 2 animals (gd 109, 120) with an ultramicrotome (Ultracut E, Reichert, Vienna, AT), mounted on copper grids and stained with uranyl acetate and lead citrate. In 6 sections of each animal, TGCs were observed with a transmission electron microscope (CM12, Philips, Eindhoven, NL) and photographs were taken with a CCD camera (Ultrascan 1000 or Orius 832, Gatan, Pleasanton CA, USA). All TGCs, which were visible in a total cross section and showed two nuclei, were photographed. By means of the photographs, the cells were assessed regarding following criteria:

- contact to the BM
- contact to the feto-maternal interface
- presence of membrane-bound granules
- occurrence of DLB

### SERIAL BLOCK FACE-SCANNING ELECTRON MICROSCOPY (SBF-SEM)

The prepared tissue of 1 animal (gd 158) was visualised in a serial block face-scanning electron microscope (FEI Quanta 250 FEG variable pressure SEM, Thermo Fischer Scientific) equipped with a Gatan 3View 2XP system and dedicated backscatter detector (Gatan, Inc., Pleasanton CA, USA). 2 areas, which contained chorionic villi, were imaged with a voxel size of 11 x 11 x 100 nm<sup>3</sup>. Images had 5000 x 5000 pixels and stacks of 1000 images were produced.

SBF-SEM images were edited with ImageJ (ImageJ, version 2.0.0-rc-43/1.51d, open source image processing software) as followed: inversion, smoothing, contrast enhancement of 0.5 %

and conversion from 16-bit dm3-data file to 8-bit tiff-data file. Image stacks were screened for BUCs, of which 1 cell was reconstructed to a three-dimensional image. Therefore, the selected cell was manually segmented with the ImageJ plugin TrakEM2. Cell nucleus, cell body and the trophoblast epithelium were segmented separately in a stack of images and a three-dimensional model was created with the Imaris x64 9.0.0 (Bitplane AG) software.

## **Results**

### **SERIAL SECTION EXAMINATION**

#### **Light microscopy (LM)**

In series of semithin sections, 63 TGCs, 20 BUCs and 65 UTCs were followed (Fig. 1 a, b) and their TNVs were determined. The TNVs of TGCs showed a wide variation and ranged from 491 to 2777  $\mu\text{m}^3$ . TNVs of BUCs and UTCs showed both a unimodal distribution and ranged from 298 to 607  $\mu\text{m}^3$  (BUCs) and from 161 to 679  $\mu\text{m}^3$  (UTCs) respectively. All measured TNVs are presented in histograms (Fig. 2 a-c). The TNV of those cells which were examined by LM and TEM are also given in tables (supplementary data: tables 1, 2 and 3).

#### **Transmission electron microscopy (TEM)**

Since the morphological characteristics within each cell type did not show distinctions between the different gestational stages, cells from several animals are not described separately. Some cells could not be unambiguously assigned to 1 cell type (TGC, BUC or UTC) based on TEM. These cells as well as cells which could be examined on ultrathin sections from only 1 semithin section, have been excluded from the ultrastructural evaluation. If the classification of the cell type differed between LM and TEM, the latter was regarded as valid.

Profiles of 32 TGCs were evaluated on ultrathin sections from 2 - 5 different semithin sections (supplementary data: table 1). In all three animals, TGCs with (n = 11) and without

(n = 17) contact to the BM were visible. All TGCs with contact to the BM did not show contact to the fetomaternal interface (Fig. 3 a, b) and only a few of them possessed membrane-bound granules (2 of 11) or DLB (1 of 11). The majority of TGCs with contact to the BM showed, subjectively evaluated, a higher amount of free cytoplasmic ribosomes compared to UTCs (9 of 11) and mitochondria were diffusely distributed within the cytoplasm (10 of 11). Approximately half of the TGCs with contact to the BM showed a thin layer of electron dense material associated with the inner surface of the cell membrane (5 of 11). This layer was either completely attached to the cell membrane, detached from the cell membrane in several places or completely detached from the cell membrane, but surrounding the main part of the cytoplasmic organelles. TNVs of all TGCs with contact to the BM ranged from 588 – 1326  $\mu\text{m}^3$ .

The majority of TGCs without contact to the BM showed membrane-bound granules (12 of 17, Fig. 4 a, b), diffusely distributed mitochondria (16 of 17) and, subjectively evaluated, a higher amount of free cytoplasmic ribosomes compared to UTCs (13 of 17). A DLB was observed in 3 out of 17 TGCs without contact to the BM. Most of these cells showed a layer of electron dense material associated with the inner surface of the cell membrane as described above (16 of 17, Fig. 4 a, b). This layer of electron dense material was thicker compared to the one described in the TGCs with contact to the BM. In 2 TGCs without contact to the BM, contact to the fetomaternal interface was visible. The TNVs in all TGCs without contact to the BM varied between 508 and 2671  $\mu\text{m}^3$ .

In 4 TGCs without contact to the fetomaternal interface, the contact to the BM could not definitely be ruled out nor confirmed while their cytoplasmic content showed similarities to TGCs with and without contact to the BM. Their TNVs varied between 2432 and 2777  $\mu\text{m}^3$ .

Ultrastructural details of 9 BUCs were evaluated on ultrathin sections from 2 - 4 different semithin sections (supplementary data: table 2). All of the followed BUCs showed contact to the BM but no contact to the maternal epithelium (Fig. 5 a - d). A DLB was visible in 2 cells

(Fig. 1 a) and no cell showed cytoplasmic membrane-bound granules or a layer of electron dense material as found in the TGCs. The Golgi apparatus was not visible in any section of BUCs and rER as well as mitochondria were rarely found in all examined BUCs. In most sections, where mitochondria were visible, they seemed to be diffusely distributed (in 8 of 9 BUCs). In 1 BUC, the amount of free cytoplasmic ribosomes was subjectively evaluated as higher compared to UTCs and, overall, nuclear-cytoplasmic ratio, also subjectively evaluated, appeared rather high in BUCs (Fig. 1 a and 5 a - d).

The morphology of 26 UTCs was evaluated on sections from 2 - 4 different semithin sections (supplementary data: table 3). All examined UTCs had contact to the fetomaternal interface and did not show membrane bound granules or DLB. Contact to the BM was visible in 23 cells while it was not (n = 1) or unclear (n = 2) represented in three cells. The distribution of mitochondria, which occurred in moderate amounts, varied between apical (12 of 26) and diffuse (14 of 26). In the majority of UTCs, electron dense material was visible in the apical cell part within the region of the interdigitating microvilli, but no layer of electron dense material was seen associated to the basolateral cell membrane (24 of 26, data not shown in supplementary data: table 3). A small Golgi apparatus was visible in 9 UTCs while small amounts of rER was seen in all UTCs.

### SINGLE SECTION EXAMINATION

Cross sections of 62 binucleate TGCs were examined with TEM in single sections of two animals (supplementary data: table 4). In the majority of these cells, no contact to the BM was visible (n = 55, Fig. 4 a, b). Most of the TGCs without contact to the BM possessed membrane-bound granules (50 of 55) and showed a layer of electron dense material associated to the inner surface of the cell membrane as described in TGCs of serial sections (41 of 55, Fig. 4 a, b). In 10 TGCs without contact to the BM, a DLB was visible and 4 of the TGCs without contact to the BM showed contact to the fetomaternal interface.

Narrow attachments to the BM were found in 4 TGCs. None of these 4 cells revealed contact to the feto-maternal interface, membrane-bound granules nor a DLB. The majority of TGCs with contact to the BM had a layer of electron dense material associated to the inner surface of the cell membrane as described in TGCs of serial sections (3 of 4). In 3 TGCs, the contact to the BM could not definitely be ruled out nor confirmed while none of them had contact to the feto-maternal interface nor a DLB. Two of these cells possessed membrane-bound granules and 1 cell showed a layer of electron dense material associated to the inner surface of the cell membrane as described in TGCs of serial sections.

#### SBF-SEM

Within the images of SBF-SEM, 3 BUCs could be followed. These cells were located in the basal part of the trophoblast epithelium without contact to the maternal epithelium and possessed one nucleus. The three-dimensional structure of one of these cells is presented in Fig. 6 a. Detailed ultrastructural morphology could not be examined due to an insufficient resolution (Fig. 6 b).

#### Discussion

In the currently generally accepted hypothesis about the origin of ruminant TGCs, a BUC would represent the direct progenitor for a TGC [Wooding, 1992; Wooding and Burton, 2008]. To the authors' knowledge, such a BUC has never been revealed so far. This is probably due to the difficulty of accessing three-dimensional information about individual cells from two-dimensional sections. In our study, we used 2 different methods to gain three-dimensional information. On one hand we performed manual serial sectioning in LM and TEM, what allowed us to evaluate the presence or absence of contact to the apical or basal epithelial surface, number of nuclei per cell as well as nuclear volume and ultrastructural

information about the cytoplasmic content. In this method, information between the examined sections, called z-plane, got lost, while we obtained detailed information in the xy-plane by high resolution. On the other hand we utilized a more modern technique, the SBF-SEM, which allowed to reduce the loss of information in the z-plane (section thickness = 100 nm) compared to serial sectioning in TEM (distance between 2 examined sections = 6  $\mu$ m). Even though, as it was necessary to view bigger areas containing chorionic villi, resolution in xy-plane had to be reduced to restrict the running-time of the SBF-SEM on a period of 62 hours. For these reasons, SBF-SEM offered more complete information about the presence or absence of contact to the apical and basal epithelial surface and enabled a clear three dimensional presentation of trophoblast epithelial cells, while cytoplasmic information was reduced. For both methods, tissue was perfused with fixative by a fetal placental vessel as the main interest was posed on the fetal trophoblast epithelium. Nevertheless, it is nicely visible on the images that the fetal epithelium and in particular the feto-maternal interface is well preserved without perfusion by a maternal placental vessel.

Even if the number of animals used in this study is relatively low, we consider the collected information as representative to answer the question posed in this study. This appears to be justified, first by the very detailed information obtained by the 2 serial-sectioning methods used in this study and, second by the fact that there are no indications about major, gestational-stage depending morphological variations within each trophoblast cell type from gestational day 45 until term [Björkmann, 1969], even though protein expression has been shown to vary within gestation [Green et al., 2000; Touzard et al., 2013].

A lack of contact to the BM is generally considered to be a distinctive feature of ruminant TGCs [Hoffman and Wooding, 1993; Wooding and Burton, 2008]. In our study, we showed for the first time that some binucleate TGCs still have narrow contact to the BM. Due to their basal location within the trophoblast epithelium and their relatively small TNVs, compared to all examined TGCs, we interpret these cells as early developmental stages of TGCs [Klisch et

al., 1999b]. These results indicate that the process of losing basal contact does not have to be completed before the cells become binucleate. Findings of previous studies showed, that alpha-keratin is localized in basally located binucleate cells, but not in mature, apically migrated cells [Lee et al., 1990]. This coincides with our results, as cytokeratin constitutes an important intracellular anchorage of hemidesmosomes, which attach epithelial cells to the BM [Alberts, 2015]. Nakano et al. [2001] showed that most bovine TGCs in culture, which expressed uniform cytoplasmic staining of PL, did not show a staining of cytokeratin. Only a very small minority of the PL-positive TGCs showed a weak staining of cytokeratin. Despite the interpretation of Nakano et al. [2001] that PL-producing TGCs did not have any cytokeratin, it seems possible for us, that this small minority of TGCs with simultaneous staining of PL and cytokeratin could correspond to TGCs found in our study showing contact to the BM as well as membrane-bound granules. Even though, as soon as PL production starts, cytokeratin expression decreases. This indicates that TGC maturation and migration is associated with a reciprocal regulation of these proteins [Nakano et al., 2001]. Therefore, as cytokeratin also represents the intracellular part of desmosomes [Getsios et al., 2004; Coch and Leube, 2016], we interpret desmosome-possessing TGCs, which have been shown by Morgan and Wooding [1983], as young stages of TGCs.

We observed an intracellular layer of electron dense material underlying the cell membrane of some TGCs and in relation to the microvilli of UTCs. Based on the ultrastructural appearance and the fact that actin is a main component of the microvilli frame in other epithelial cells [Fath and Burgess, 1995; Coch and Leube, 2016], we interpret this electron dense material in both cell types as a part of the actin cytoskeleton. This interpretation is reinforced by immunogold [Lang et al., 2004] and immunohistochemical stainings [Nakano et al., 2005]. Actin [Lang et al., 2004] as well as  $\alpha 6$  and  $\beta 1$  integrin subunits and laminin [Pfarrer et al., 2003] have been suggested to be involved in TGC migration. As  $\alpha 6 \beta 1$  integrin, also called very late antigen-6 (VLA-6) [Hemler et al., 1988], can interact indirectly with actin

intracellularly [Alberts, 2015] and with laminin extracellularly [Sonnenberg et al., 1988; Alberts, 2015], the simultaneous staining of laminin and  $\alpha 6$  and  $\beta 1$  integrin subunits along the cell membrane of TGCs lead to the interpretation that these proteins cooperate in TGC migration [Pfarrer et al., 2003]. Laminin and  $\alpha 6 \beta 1$ -integrin dependent cell movement has also been described in epithelial cancer cells [Tani et al., 1997]. Another protein, which might be involved in TGC migration, is E-cadherin [Nakano et al., 2005]. Nakano et al. [2005] interpreted their findings of redistribution of E-cadherin from the membrane-associated location to the cytoplasm in TGCs to play a role for TGC migration apically of tight junctions. Down-regulation of membrane-associated E-cadherin has been described as an event during epithelial-mesenchymal transition (EMT) in other tissues [Morali et al., 2001; Yang and Liu, 2001]. EMT plays an important role in different biological processes such as fetal development, tumour metastasis, renal interstitial fibrosis [Yang and Liu, 2001; Thiery, 2002; Yang and Weinberg, 2008] as well as in the development of extravillous cytotrophoblast of the human placenta [Vicovac and Aplin, 1996; Davies et al., 2016]. Based on the above-mentioned findings of Nakano and co-authors [2005], EMT might also play a role in the development of bovine TGCs.

The presence of a BUC could be confirmed in all evaluated animals. Based on morphological characteristics, we assume that these BUCs are the precursors of TGCs. Since TGCs migrate from the basal part of the trophoctodermal epithelium towards the maternal tissue [Wathes and Wooding, 1980; Wooding and Wathes, 1980; Wooding, 1983], it appears obvious that their direct progenitor is located within the basal part of the epithelium. Further, BUCs tend to have narrow contacts to the BM (Fig. 5b, c), assuming that these cells are in the process of losing contact to the BM, as it would be necessary for the development of TGCs. Additionally, a DLB, which has been described to be a characteristic structure of TGCs [Wooding and Burton, 2008], was shown in 2 BUCs.

414 According to Wooding and his co-authors [Wooding, 1992; Wooding and Burton, 2008],  
415 these BUCs would represent a transient cell between UTCs and TGCs. UTCs are  
416 morphologically and functionally distinct from TGCs [Igwebuike, 2006]. Consequently, such  
417 a development would be a transdifferentiation process, in which one differentiated cell  
418 undergoes a dedifferentiation into another specialized cell type [Rawlins and Hogan, 2006].  
419 Differentiated cells have been shown to possess the ability for transdifferentiation in several  
420 other organs [Gordon and Lane, 1984; Michalopoulos et al., 2005].

421 In epithelial tissues that need continuous cell supply, proliferating cells can be separated into  
422 2 groups: cells which show slow cycling activity and cells which show fast cycling activity.  
423 The slowly cycling cells are interpreted to be the tissue specific stem cells, which have the  
424 capability for self-renewal and give rise to cells of the second, fast cycling group. These fast  
425 cycling cells, the so-called “transit-amplifying” cells, have a reduced ability of self-renewal  
426 and arrange primarily supply to the sufficient number of specialized cells by progressive step-  
427 by-step differentiation and maturation [Lajtha, 1979; Potten and Loeffler, 1990; Tsujimura et  
428 al., 2002]. Transferred to the bovine trophoblast epithelium, it could be hypothesized that the  
429 UTCs, which show proliferative activity [Schuler et al., 2000], represent this “transit-  
430 amplifying” cell population and ensure the TGC ordnance by transdifferentiating. Findings of  
431 heterogeneous immunohistochemical staining of UTCs [Nishita et al., 1990] may reflect the  
432 step-by-step differentiation of these “transit-amplifying” cells. It remains open whether a slow  
433 cycling progenitor cell exists for the “transit-amplifying” UTCs.

434 Alternatively, it could be hypothesized that the BUCs represent a distinct stem cell population  
435 for the TGCs. Their basal localization within the trophoblast epithelium is reminiscent of  
436 epithelial stem cells in other tissues [Marei and Abd El-Gawad, 2001; Kurzrock et al., 2008].  
437 Furthermore, their ultrastructural appearance, which has been assessed subjectively, seems to  
438 represent a rather high nuclear-cytoplasmic ratio and spare rER and mitochondria. These  
439 properties bear resemblance to the basal progenitor cells of the respiratory tract [Marei and

Abd El-Gawad, 2001]. Since we did not detect a Golgi apparatus in any of the BUCs, it is likely that these cells have only a small sized Golgi apparatus with low productivity. These observations raise the question as to whether BUCs could represent a cell population that differentiates into TGCs without having their origin in UTCs (Fig. 7 b). As no sign for fast cycling cells between BUCs and TGCs have been observed, in this new theory, BUCs would differentiate directly into post mitotic TGCs without morphological different “transit-amplifying” cells. There remains the option that the BUC population itself can be divided in a slow cycling cell group and a “transit-amplifying” cell group. To verify this hypothesis, further investigations would be needed, for example the combination of staining with proliferation marker and three-dimensional imaging.

In conclusion, we show that there is a basally located uninucleate cell type within the bovine trophoblast epithelium. The presence of such a cell type as an intermediate state between UTCs and TGCs has previously been postulated, but has never been revealed [Wooding, 1992; Wooding and Burton, 2008]. Based on morphological findings, we suggest, in accordance with Wooding and his co-authors [Wooding, 1992; Wooding and Burton, 2008], that the BUCs are the progenitor cells of TGCs. To clarify the question whether the BUCs themselves develop from UTCs [Wooding, 1992; Wooding and Burton, 2008] or if they are a separate self-replicating cell population (Fig. 7 a, b) needs further investigations.

## **Acknowledgements**

The authors thank Miriam Lucas-Droste, Scientific Center for Optical and Electron Microscopy, ETH Zurich, for her guidance and the production of SBF-SEM images and to Moritz Kirschmann, Center of Microscopy and Image Analysis, University of Zurich, for his support with the image processing and 3D-modelling. We are grateful to Elisabeth Hoegger

and Elisabeth Schraner, Institute of Veterinary Anatomy, University of Zurich, for their technical advices and support with the light and electron microscopical imaging and Lutz Slomianka, Institute of Anatomy, University of Zurich, for his guidance and support with stereology. We also thank Jeanne Peter, Vetcom, University of Zurich, for graphical illustrations.

608  
609 **Fig. 1 a, b.** Bovine trophoblast epithelium in serial sections of semithin sections in light  
610 microscopy (LM) and an intermediate ultrathin section in transmission electron microscopy  
611 (TEM) (FS: fetal stroma, FV: fetal vessel, ME: maternal epithelium, bars = 5  $\mu$ m).

612   **a** Serial sections of a basally located uninucleate cell (BUC: asterisk) in LM (sections 47 –  
613   63) with an intermediate TEM section (section 48). The inset in the TEM image of section 48  
614   shows, that the BUC has contact to the basement membrane (BM: black arrows, contact is  
615   shown between black arrowheads in the inset at higher magnification) and a double lamellar  
616   body (DBL: white arrow). No contact to the feto-maternal interface (open arrowheads) was  
617   visible in the examined semithin or ultrathin sections and the nuclear-cytoplasmic ratio seems,  
618   subjectively evaluated, to be rather high (gd 140).

619   **b** Serial sections of a binucleate trophoblast giant cell (TGC: asterisk) in LM (sections 39 –  
620   55) with an intermediate TEM section (section 48). This TGC shows contact to the BM (black  
621   arrows, contact is shown between black arrowheads in the inset at higher magnification). No  
622   contact to the feto-maternal interface (open arrowheads) was visible in the examined semithin  
623   or ultrathin sections (gd 140).

624

625

**Fig. 2 a-c.** Total nuclear volume (TNV in  $\mu\text{m}^3$ )

**a** Trophoblast giant cells (TGCs) show a wide variation of TNVs. Two peaks at about 600 and 2400  $\mu\text{m}^3$  are visible, which most likely correspond to TGCs with DNA contents of 2 x 2C and 2 x 8C [Klisch et al., 1999a; Klisch et al., 1999b].

**b** Basally located uninucleate cells (BUCs) and **c** uninucleate trophoblast cells (UTCs) show a unimodal distribution of TNVs with lower values compared to the TGCs.

**Fig. 3 a, b.** Trophoblast giant cells (TGCs: asterisk) with contact to the basement membrane (BM: black arrow, contact is shown between black arrowheads in the inset at higher magnification). None of the TGCs with contact to the BM was in tangency to the fetal-maternal interface (FS: fetal stroma, bars = 5  $\mu$ m).

**a** A binucleate TGC (asterisk) which reveals 2 narrow, tapered areas with contact to the BM (between black arrowheads, gd 140).

**b** A binucleate TGC (asterisk) which reveals a narrow, tapered contact to the BM (between black arrowheads, gd 109).

**Fig. 4 a, b.** Transmission electron microscopic sections of binucleate trophoblast giant cells (TGCs: asterisk) without contact to the basement membrane (BM: solid black arrow) and showing membrane bound granules (small black arrow) as well as intracellular electron dense material attached to the cellular membrane (white arrowheads). The areas in boxes are shown at higher magnification in the insets (FS: fetal stroma, FV: fetal vessel, TE: trophoblast epithelium, UTC: uninucleate trophoblast cell, open arrowheads: feto-maternal interface, bars = 10 μm).

**a** A binucleate TGC showing an apical protrusion (x), which is getting in contact with the maternal epithelium (ME). Along the inner surface of the cell membrane, a layer of electron dense material (white arrowheads) is visible, which excludes the apical protrusion (shown in the inset at higher magnification, gd 109).

**b** A binucleate TGC close to the maternal epithelium (ME). A layer of electron dense material (white arrowheads) is attached to the inner surface of the cell membrane (shown in the inset at higher magnification, gd 140).

**Fig. 5 a-d.** Morphology of basally located uninucleate cells (BUCs: asterisk) of the bovine trophoblast epithelium. Contact to the basement membrane (BM: black arrows), which was visible in all examined BUCs, is shown at higher magnification in the insets. Nuclear-cytoplasmic ratio seemed, subjectively evaluated, to be rather high in BUCs. No examined BUC was in tangency with the feto-maternal interface (FS: fetal stroma, FV: fetal vessel, bar = 5  $\mu$ m).

**a, d** A BUC with laminar contact to the BM (between black arrowheads, gd 214 and 140).

**b, c** A BUC with a petiolate contact to the BM (between black arrowheads, gd 140).

**Fig. 6 a.** Three-dimensional model of a basally located uninucleate cell (BUC), based on serial block face-scanning electron microscopical images of the bovine trophoblast epithelium. The cell has several basal processes and is attached to the basement membrane (BM). No contact to the apical surface of the trophoblast epithelium (arrowhead) is present (bar = 5  $\mu$ m, gd 158).

**b** Serial block face-scanning electron microscopical image of the same cell as in image A of this figure.

**Fig. 7.** Schematic drawings of 2 potential modes of the formation of basally located uninucleate cells (BUCs) in the bovine trophoblast epithelium. The fetal trophoblast epithelium is drawn on top, the maternal uterine epithelium is below.

**a** A typical UTC (1) undergoes an asymmetric mitosis (2) which leads to 2 different cells; 1 apically located cell and 1 basally located cell (BUC) (3). This latter cell gradually reduces the contact to the basement membrane (4 and 5).

**b** A basally located stem cell (yellow cell: 1) is present in the trophoblast epithelium. This cell performs a self-renewing asymmetric mitosis (2), which leads to 1 stem cell (yellow cell: 3) and 1 BUC (4).

## Supplementary data

Table 1: TNV and ultrastructural characteristics of TGCs examined on serial sections, sorted after increasing TNV. (BM = basement membrane, FMI = feto-maternal interface, MBG = membrane-bound granules, FCR = free cytoplasmic ribosomes (compared to UTCs), LEDM = layer of electron dense material)

TNV ( $\mu\text{m}^3$ )	Contact to the BM	Contact to the FMI	Presence of MBG	Presence of DLB	Distribution of Mitochondria	Amount of FCR	Presence of a LEDM
508	no	no	no	no	diffuse	higher	yes

## Curriculum Vitae

Vorname Name	Jeannette Attiger
Geburtsdatum	28. September 1989
Geburtsort	Wetzikon ZH
Nationalität	Schweiz
Heimatort bei Schweizern	Wetzikon ZH
08/2002 – 08/2008	Kantonsschule Zürcher Oberland, Wetzikon ZH
28.08.2008	Maturität (Kantonsschule Zürcher Oberland, Wetzikon (CH))
09/2009 – 08/2014	Studium der Veterinärmedizin Vetsuisse-Fakultät, Universität Zürich (CH)
30.12.2014	Diplom med. vet. Vetsuisse-Fakultät, Universität Zürich (CH)
02/2015 – 05/2018	Anfertigung der Dissertation unter Leitung von PD Dr. med. vet. Karl Rüdiger Klisch Veterinär-Anatomisches Institut der Vetsuisse-Fakultät, Universität Zürich (CH) Direktor: Prof. Dr. Alois Boos
02/2015 – 04/2017	Assistenz in der Veterinär-Anatomischen Lehre Veterinär-Anatomisches Institut der Vetsuisse-Fakultät, Universität Zürich (CH)
05/2017 bis heute	Assistentztierärztin, Tierklinik Lindenhof, Bischofszell (CH)
